54 Apparatus and method for compensating a raster scanner for component deficiencies.

57 Apparatus and method for compensating a raster scanner for component deficiencies which includes a defocused calibration strip (900) which is scanned to provide shading signals for calibrating the individual scanning elements of an array (40, 41), the shading signals being processed in successive blocks each of which comprises a preset number of shading signals. Following processing, the shading signals are stored in memory (926) and accessed during normal scanning. The shading signals are employed in all operational modes to compensate the image signals produced by the scanner (10) for deficiencies in the scanning components. Additionally, bad or defective scanning elements are detected and on read out of image signals skipped and the image signal from the preceding scanning element substituted.

FIG. 33

APPARATUS AND METHOD FOR COMPENSATING  
A RASTER SCANNER FOR COMPONENT DEFICIENCIES

This invention relates to apparatus and method for compensating a raster scanner for component deficiencies, and particularly for compensating image signals produced by the scanner for deficiencies in scanner illumination and optical components.

In raster scanners employing one or more scanning arrays, the light received by the array or arrays may be irregular or non-uniform across the scan line. Such irregularity and non-uniformity, the spatial frequency of which is low, may be due to inherent scan lamp characteristics and profile, irregularities in the lamp reflector surfaces, vignetting of the image rays, refraction at large field angles, etc. As a result, the output of the light sensors or photosensitive elements that comprise the scanning array or arrays may not be at a uniform level and hence will not necessarily give an accurate indication of the relative illumination of the image portion scanned.

In this context, it will be understood that the signal output of the sensors of an array is directly influenced by the amount of illumination received from the document being scanned. This in turn is influenced by the amount of illumination applied to the document by the scan lamp, and the efficacy of the optical system in transmitting the image rays to the array. Where the illumination level is not consistent across the scan line, and or where optical system transmission is not uniform, substantial differences in the signal levels generated by the various sensors of the array can occur with resulting image degradation and inaccuracy.

In a similar vein, the arrays may have sensors that are defective. Often this results from deficiencies in the manufacturer's quality control procedures brought on in part by the desire to pack as many sensors or photosensitive elements as possible on the smallest sized chip. Indeed, in some present day arrays, the number of sensors on the chip exceeds 1700. Since the cost of scanning arrays is still relatively high and the job of physically replacing an array, particularly in the field where the necessary optical alignment instruments and knowhow may not be available, difficult, it would be highly advantageous to be able to use arrays with defective or below par sensors rather than replace them.

In another aspect, it can be understood that the several components that make up the optical system, i.e. the platen on which the original image to be scanned is placed, the lens or lenses, and mirror or mirrors may also have or in use acquire slight defects of damage, typically scratches. As in the case of a defective scanning array, it would be highly advantageous to be able to use the slightly damaged optical part without going to the expense and trouble of replacing or refurbishing the affected part.

The invention as claimed is intended to provide a remedy by compensating for variations in light to which individual image sensors of a scanning array are subjected, and bypassing array sensors that are defective. A separate test signal from each sensor in the array is produced by scanning a test image of predetermined optical density; the sensors are segregated into groups, each group being composed of a preset number of sensors; the test signals from each of the sensor groups averaged to provide a composite compensating signal for each sensor group which is stored, and the signal output of each sensor corrected using a stored compensating signal for the sensor group for that sensor. Defective sensors are identified and on reading out of the image signals from the array, readout of the defective sensors is skipped and the readout of an adjoining sensor substituted.

The present invention will now be described by way of example with reference to the accompanying drawings, in which:

For purposes of description, the image input terminal 10 (hereinafter IIT) is conveniently divided into scanner section 12 for raster scanning an original document (Figures 1-7), a document handler 14 for bringing documents 8 to be scanned into registered position on platen 28 of scanner 12 (Figures 8-13), and control processing section 16 containing the various electronic components and circuits for controlling operation of scanner 12 and document handler 14, and for processing the image signals generated (Figures 14-36).

Referring particularly to Figures 1-4, scanner 12 includes a frame or housing 18 consisting of base 20, side walls 21,22, front and rear walls 24,25, and top wall 26. Base 20 and walls 21,22, 25,26 cooperate to form an interior chamber or compartment 27 within which a movable scan carriage 32 is disposed. Base 20 and walls 21, 22, 24, 25, 26 of housing 18 are planar, top wall 26 including a generally rectangular transparent glass or platen 28 through which the original document 8 to be scanned is viewed.

Document handler 14 normally overlays platen 28, the document handler 14 serving to bring one document at a time forward into registered position on platen 28. Following scanning of the document, the document is removed by document handler 14 to clear platen 28 for the next document as will appear more fully herein. Where document handler 14 is not used, the document to be scanned, i.e. a book (See Figure 13) is manually placed on platen 28 in registered position. Following completion of scanning, the document is manually removed. In this mode of operation, document handler 14 is swung to an out-of-the way position or removed. See Figure 11. Preferably where document handler 14 is removed, a suitable platen cover (not shown) is provided to prevent glare and permit platen 28 to be covered when not in use to protect the surface thereof from scratches, dust, etc.

The portion 30 of top wall 26 between the end of platen 28 and front wall 24 is preferably beveled or sloped downwardly to provide a supporting surface facilitating scanning of bound originals such as books.

Scan carriage 32 is supported for longitudinal movement (in the Y direction) within compartment 28 of scanner 18 by means of parallel carriage support rods 34,35. Carriage support rods 34,35 are carried in front and rear walls 24,25 of housing 18. To support carriage 32 on rods 34,35, front and rear journals or bearings 36 are provided on the sides of carriage 32, bearings 36 slidably riding on rods 34,35.

To impart scanning motion to carriage 32, a drive screw 37 is threadedly engaged with carriage 32 via nut 38. Reversible drive motor 39, which is supported on base 20 of housing 18 adjacent rear wall 25, drives screw 37 in either a clockwise (scan) or counter-clockwise (return) direction to move carriage 32 longitudinally along carriage support rods 34,35.

A pair of scanning or image arrays 40,41, which may for example, comprise Fairchild Model 121 H CCD Chips, are supported on carriage 32 adjacent one end thereof in predetermined spaced relation such that array 40 is above and to one side of array 41. Arrays 40,41 each comprise a series (e.g. 1728) of individual photosensitive elements effective when exposed to the document being scanned to generate a signal whose potential is proportional to the reflectance of the image area seen by the array element.

An optical system consisting of lens 55, scan mirror 56, and reflecting mirrors 57,58,59, cooperate to form an optical path 54 through which image rays reflected from a document on platen 28 are transmitted to arrays 40,41. Lens 55 is mounted substantially centrally on carriage 32 in preset spaced opposing relation to arrays 40,41. Mirrors 56,57,58,59, which are generally rectangular in configuration, are mounted on carriage 32 in preselected angular dispositions to provide a folded optical path between platen 28 and lens 55. Mirror 59 has two facets 61,62 disposed at predetermined angles with respect to one another such that mirror 59 serves as an object beam splitter to split the projected image into two images, one for each array 40,41. During scanning, image rays reflected from the document on platen 28 pass downwardly to scan mirror 56 and from scan mirror 56 through mirrors 57,58,59 to lens 55 and arrays 40,41.

To illuminate platen 28 and any document thereon, an elongated exposure lamp 65 is provided on carriage 32. Lamp 65 which extends in the direction generally perpendicular to the direction of movement of scan carriage 32, is disposed in a generally cylindrical lamp housing 66. A slit-like exposure aperture 67 in lamp housing 66 extends across the width of platen 28. The interior walls 69 of lamp housing 66 are preferably polished to reflect light from lamp 65 toward aperture 67 and platen 28.

A reflector 70 is provided opposite aperture 67 to further reflect light emitted by lamp 65 onto platen 28 adjacent the image scan line. Reflector 70, which is disposed on the opposite side of optical path 54, is pivotally supported by pins 72 on carriage 32. Spring 73 biases reflector 70 in a counter clockwise direction into engagement with fixed locating stop 74 on carriage 32. The upper surface of reflector 70 is beveled at 75 and cooperates with the downwardly sloping interior portion 30 of top wall 26 on movement of carriage 32 to a home position to pivot or swing reflector 70 forwardly (to the dotted line position shown in Figure 4).

During operation, lens 55 and mirrors 56,57, 58,59, and exposure lamp 65 and reflector 70, move (in the Y direction shown by the solid line arrow of Figures 2 and 3) from the carriage home position to the end of scan 81 to scan the document 8 on platen 28. Light from exposure lamp 65 illuminates a line-like area i.e. the scan line, across the width of platen 28 (in the X direction shown by the dotted line arrow of Figure 3). As carriage 32 moves under platen 28, the line-like illuminated area travels the length of platen 28. Following completion of the scan, carriage 32 returns to the home position.

Referring particularly to Figures 5, 6, and 7, arrays 40,41 comprise generally rectangular chips 100, the internal photosensitive or viewing elements of which extend longitudinally thereof to form a narrow viewing window 102. An adjustable array support assembly 101 is provided for each array. Each support assembly 101 includes a chip carrier 104 to which the array chip 100 is suitably attached as by means of adhesive. Carriers 104 are in turn attached to upper and lower floating blocks 106,108 respectively as by means of screws 109.

Blocks 106,108 are generally T-shaped with a central generally rectangular aperture 111 over which the array is secured, with outwardly extending side projections 112,113. One interior face 115 of each projection 112,113 rests against an adjustable support 116,117. In the arrangement shown, upper block 106 is inverted relative to lower block 108 with the result that supports 116,117 for upper block 106 ride against the upper side 115 of projections 112,113 of block 106 while the supports 116,117 for lower block 108 ride against the lower surface 115 of projections 112,113 and block 108. Supports 116, 117 each comprise a threaded member 120 bearing a contact pad 121 at one end thereof for engagement with the surface 115 of the block 106,108 associated therewith.

Supports 116,117 are threadedly engaged in generally U-shaped upper and lower block support plates 124,126 respectively. Plates 124,126 are in turn attached as by means of screws 127 to base members 128,130 respectively. Springs 132 bias blocks 106,108 toward and into engagement with the supports 116,117 associated therewith. See Figure 7.

As will be understood, rotation of threaded members 120 of supports 116,117 displaces the block 106, 108 and array 40,41 associated therewith in a generally vertical direction to raise or lower the array

relative to the optical path against the bias of spring 132. Rotation of the threaded member of support 116 or 117 only, or simultaneous rotation of the threaded members of both supports 116,117 in opposite directions, effects a rotation or turning movement of the array supporting blocks to adjust the angle of the array relative to the horizontal.

To provide for adjustment of arrays 40,41 in a direction parallel to the horizontal, an adjustable support 140,142 is threadedly disposed in the upstanding end of each plate 124,126 with contact pads 121' thereof projecting into engagement with the outer end of projections 113 of upper and lower blocks 106,108. Spring 143 (Seen in Figure 7) biases blocks 106,108 axially into contact with the adjustable support 140,142 associated therewith.

Rotation of the threaded member 120' of support 140 or 142 displaces the block 106,108 associated therewith axially in a direction parallel to the horizontal against the bias of spring 143 to adjust the position of the array 40 or 41 relative to the optical path.

Each array support assembly 101 is attached to the scan carriage frame 52 opposite lens 55 by means of a pair of externally threaded screw members 152,154 and cooperating locking screws 160. Screw members 152 and 154 are threadedly engaged in internally threaded blocks 156,158 carried on carriage frame 52. The terminal ends 151 of screw members 152,154 facing the array support assemblies 101 are hollow and internally threaded at 159 for receipt of the externally threaded locking screws 160. Spacers 161 and spring washers 162 are provided on each blocking screw 160 to position the array support assemblies in predetermined lateral position relative to the locking screws. Holes 164,165 in base members 128,130 of array support assemblies 101 permit locking screws 160 to pass therethrough into threaded engagement with screw members 152,154.

A generally spherically shaped recess 170 is provided in the face of each base member 128,130 coaxial with hole 164. A vertical generally V-shaped recess 171 is provided in the face of each base member 128,130 opposite hole 165. The terminal end 151 of screw member 152 is rounded off for receipt in recess 170 of base member 128,130. Screw member 154 has a vertical semi-circular segment 174 rotatably disposed on the terminal end thereof for receipt in V-shaped recess 171 of block members 128,130.

Alignment of arrays 40,41 perpendicular to the optical path and focusing thereof is effected by selective rotation of screw members 152,154

following attachment of the array support assemblies 101 to the ends of screw members 152,154 and the carriage frame 52 by locking screws 160. Tightening of locking screws 160 draws the spherical end of screw member 152 in the spherical recess 170 and segment 174 on screw member 154 into V-shaped recess 171.

Simultaneous rotation of both screw members 152,154 in the same direction moves the array support assembly 101 toward or away from lens 55 to adjust the array focus. Rotation of screw member 152 only causes the array support assembly 101 to pivot or rotate about the cylindrical segment 174 on screw member 154 to adjust the angular disposition of the array support assembly 101 relative to the optical path. To shield arrays 40,41 from extraneous light, a flexible diaphragm 175 is disposed between lens 55 and the array support.

Referring now to Figures 8-10, document handler 14 includes a generally rectangular frame member 200 on which cooperating document input pinch rolls 201,202 are rotatably supported. Upper pinch rolls 201 are carried on input roll drive shaft 204 journaled in sides 205,206 of frame member 200. The lower pinch rolls 202 are supported in cantilever fashion by spring members 207 secured to the rear wall of frame member 200. Pinch rolls 201,202, which are selectively disengageable so that a document 8 to be scanned may be readily placed between them, cooperate to advance the document inserted into document feed slot 210 in cover 24 forward to a wait station whereat the document is preregistered. For this purpose, a pivotally supported registration gate 212 with cooperating pivotally supported upper chute 214 is provided.

Gate 212, which includes plural spaced apart registration stop fingers 216, is supported on shaft 217 so that the fingers 216 project through openings 218 in frame member 200. Upper registration chute 214 is also arranged to be pivoted about a shaft 220 on frame member 200. When registration fingers 216 are in their operative or raised position, chute 214 is lowered to limit the thickness of a document which can be inserted in document feed slot 210. Chute 214 is biased downwardly (in a counter-clockwise direction) about the pivot axis of shaft 220 by gravity.

Upper chute 214 includes arm 222 coupled via adjustable set screw 223 to actuating member 224. Solenoid 225 is driveably connected to actuating member 224.

In operation, where solenoid 225 is not actuated, spring 2 biases registration gate pivot shaft 217 so that gate 212 is raised to intercept the leading edge of the document inserted into the document feed slot 210. On a disposition of a document in document slot 210 and against the registration fingers 216, solenoid 225 is actuated to lower the registration fingers 216. At the same time input rolls 201, 202 close to advance the document sandwiched therebetween forward into the nip of document transport belt 230. It will be understood that actuating member 222 connected to the registration member pivot shaft 217 works through screw 223 to pivot chute 214 upwardly to facilitate movement of the document therethrough.

Platen transport belt 230 is supported within the frame assembly 200. Frame assembly 200 is pivotally supported at one side by platen 28 by input pinch roll drive shaft 204.

The platen belt transport 230 is comprised of a single belt which is stretched about the input drive pulley 232 and the exit idler pulley 233. Both input and exit pulleys 232, 233 are journaled for rotation in sides 205, 206 of frame assembly 200. Internally of the belt 230 an input backup roll 235 is pivotally supported. Input backup roll 235 is rotatably arranged at one end of a frame member 236 which in turn is pivotally supported about shaft 238 secured between sides 205, 206 of the frame assembly 200. A second pivotally supported frame member 240 is pivotally arranged at the other end about shaft 238 and rotatably supports a registration backup roll 241 at its free end.

Backup rolls 235, 241 are urged against the interior of belt 230 by the weight of the parts to obtain the requisite driving force between belt 230 and the document 8 being advanced.

Platen belt transport 230 advances the document 8 onto platen 28 and against platen registration edge 29 to register the document in position for scanning by scanner section 12. Referring particularly to Figure 8, registration edge 29 comprises a plate-like member 250 which is comparatively thin and sufficiently flexible to conform to the beveled wall 30 adjoining the front edge of platen 28. Registration edge 29 is supported for movement in a plane parallel to beveled wall 30 to enable edge 29 to be retracted after the document has been registered. This permits the document to be removed from the platen 29 at the end of the copy cycle.

Springs 252 bias the registration member 250 against the platen edge. The registration member 250 is arranged for sliding movement on the registration gate frame 254. Tension springs 255 bias registration member 250 toward a retracted position against stop member 256, member 250 being slotted at 258 for receipt of stop members 256. Registration member 250 is raised to bring the registration edge 29 thereof into position to intercept the leading edge of the document by means of a solenoid 260 which is connected to member 250 by link 262.

When raised to the document intercept position, the register edge 29 engages belt 230 to raise the register backup roll 241 slightly off of the surface of platen 28 to create a registration pocket. This reduces the normal force of belt 230 against the document as the document is advanced toward register edge 29.

After the document has been registered, solenoid 260 is engaged and register edge 29 is withdrawn to the retracted position shown in Figure 8. This permits register roll 241 to drop back into engagement with the document through the belt 230 to facilitate advance of the document from platen 28 by the belt transport 230. If a second document has been preregistered against fingers 216, the document is fed onto platen 28 simultaneously with the removal of the previous document from platen 28.

The document is advanced by transport belt 230 into the nip of output roll pair 265, 266. Roll 265 is supported on rotatable output roll drive shaft 268. Lower rolls 266 are idler rolls and are supported on individual shafts 269. Spring 270 biases rolls 266 into engagement with the rolls 265. Guide chutes 272, 273 serve to guide the document into the nip of rolls 265, 266 and through discharge opening 275 to document tray 266.

To permit document 8 to be located in registered position on platen 28 manually, a document register edge 282 is provided. Referring particularly to Figures 11, 12, parallelogram type linkage 284, secured to frame 200 provides parallel sliding movement of registration plate 283. Tension springs 287 bias the parallelogram linkage 284 such that the registration edge 282 thereof is in operative position on platen 28. Cable 288 couples linkage 284 to actuating member 289 mounted on the document handler cover 24.

When document handler 14 is raised, cable 288 is slack and manual registration edge 282, under the influence of springs 287, is

operatively positioned on platen 28 to register a document placed thereon. When document handler 14 is closed, actuating member 289 pulls cable 288 taut to retract registration edge 282 to an out-of-the way position.

Referring particularly to Figures 9 and 11, a drive motor 290 is connected to document handler 14 via clutch and pulley 291, timing belts 292 and 293, and intermediate pulley pair 294 as shown in Figure 11. Timing belt 293 is coupled to shaft 204 of roll 201 through pulley 296. Timing belts 297 and 298 couple shaft 204 to pulley 299 on platen transport belt drive roll 23 and pulley 300 of document discharge rolls 265.

Referring to Figure 13, a pivotally supported document decelerator support bar 302 is provided in tray 266. Spring 303 biases bar 302 upwardly. Mylar (trademark) strips 305 on bar 303 serve to decelerate documents exiting from document handler 14.

Referring to Figure 14, control section 16 may be conveniently divided into CCD sensor board (SB) 300, scan electronics module (SEM) 302, image processing module (IPM) 304, video output board (VOB) 306, MPU controller board (MPU) 308 and operator control panel 309. As will appear more fully herein video image signals or pixels produced by arrays 40,41 are initially processed on SB 300 following which the analog image signals are input to IPM 304 for further processing. Processing of the image signals is regulated by clock signals derived from SEM 302 and commands from MPU 308. MPU 308 in turn, responds to instructions by the user through control panel 309.

Following processing, the image signals, are output by IPM 304 to VOB 306. From VOB 306 the image signals may be further processed and/or stored in memory, transmitted, or input to a suitable copy producing apparatus, the latter to provide copies of the document or document originally scanned.

IIT 10 is operable in one of several modes in accordance with the instructions of the user or operator. In addition, a DEFAULT MODE is automatically invoked whenever a system overload occurs, as for example when compressing the image signals.

The operational modes of IIT 10 comprise a LINE INPUT MODE, PICTORIAL INPUT MODE, PICTORIAL ENHANCEMENT MODE

and DEFAULT MODE. The LINE INPUT MODE is used to scan documents which are comprised mainly of line type graphical information. In this mode, the analog image signals are compared with a preset threshold value to provide an image signal output by IIT 10 in binary (i.e. 1 bit per pixel) form. Scanning is effected at a relatively high speed and image output resolution after processing is relatively high. One scanning speed is 125 mm per second (mmps) for both scan carriage 32 (Y-direction) and arrays 40,41 (X-direction). This results in an image resolution of nine pixels per mm (in the X direction) by 18 lines per mm (in the Y direction). Interpolators 510, 512 and Sampler 590 (Figures 23, 24) cooperate to double the number of pixels (in the X-direction) to 18 pixels per mm as will appear. Scale coefficient latch 731 (Figure 25) permits dropping of selected pixels to provide reduced size images as will appear.

The PICTORIAL INPUT MODE is used for scanning documents containing predominantly continuous tone pictorial information. In this mode, scanning is conducted at a relatively low speed. One suitable scanning speed is 50 mmps for both scan carriage 32 and arrays 40,41. This results in image resolution during scanning of nine pixels per mm (in the X direction) by 18 lines per mm (in the Y direction). As in the case of the LINE INPUT MODE, the image signals are interpolated to double the image resolution in the X direction. This results (in the example given) of an image output resolution of 18 pixels per mm (in the X direction) by 18 lines per mm (in the Y direction). In this mode of operation, the analog image signals are screened electronically to provide a binary (i.e. 1 bit per pixel) output.

The PICTORIAL ENHANCEMENT MODE is used for scanning documents containing predominantly half tone pictorial information or continuous tone pictorial information where it is desired to retain gray scale information for subsequent processing. In this mode, scanning is done at a relatively low speed in both X and Y directions with reduced image resolution. For example, in this mode scanning may be at a rate of 50 mmps for scan carriage 32 and at the rate of 25 mmps for arrays 40,41. This results in an image resolution of nine pixels per mm (in the X direction) by nine lines per mm (in the Y direction). The image output is quantized, coded 6 bit gray scale as will appear.

The DEFAULT MODE may occur when an overload is detected on the system. In response thereto, a rescan of the document is

automatically requested with interpolation omitted. Rescanning is effected at a relatively high speed, for example at 15 mps with resolution of 9 pixels per mm (in the X direction) by 18 lines per mm (in the Y direction). The output is in 1 bit binary form from either thresholding or screening, depending on the operational mode selected.

Referring particularly to Figures 15 and 16, the exemplary CCD type arrays 40, 41 each include a succession (i.e. array) of photosensitive elements 311 on the narrow center portion of silicon chip 313. Elements 311 are flanked on either side by rows 315, 316 of transfer gates 318. Registers 320, 321, which comprise parallel input-serial output analog registers, are disposed on either side of the rows 315, 316 of transfer gates.

Transfer gates 318 switch the output of the individual photosensitive elements 311 to phase gates 322 of shift registers 320, 321. The total number of transfer gates used in each row 315, 316 is equal to one half the total number of photosensitive elements 311 with alternate, i.e. odd numbered photosensitive elements coupled through row 315 of transfer gates to shift register 320 and even numbered photosensitive elements coupled through row 316 of transfer gates to shift register 321.

The total number of phase gates 322 in shift registers 320, 321 is equal to the number of photosensitive elements 311 that comprise each array and as a result, only alternate shift register phase gates are coupled to the photosensitive elements 311. Arrays 40, 41 function to convert the graphical image of a document 8 to a series of electronic image signals or pixels. On exposure of the photosensitive elements 311 to the illuminated document over a preset time interval (termed the "integration" period), a charge proportional to the luminous energy reflected from the document is generated. Following integration the charges on the photosensitive elements are transferred en masse to phase gates 322 of shift registers 320, 321 on enablement of transfer gates 315, 316 by a transfer signal  $\phi_{XA}$ ,  $\phi_{XB}$ .

Following transfer of the charges from the charge-coupled cells to alternate gates of registers 320, 321, the resulting image signals are shifted by means of clock driving pulses  $\phi 1-1$ ,  $\phi 2-1$ ,  $\phi 1-2$ ,  $\phi 2-2$  (Figure 16) serially along registers 320, 321 (i.e. from left to right in Figure 15) to output gate 326. There image signals and offset signals from the matching phase gates of the adjoining registers are summed and output via holding diode 328

of amplifier section 329 to emitter followers 333 (Figure 17) where initial signal processing commences.

Referring particularly to Figures 16, 17, image signals produced by arrays 40, 41 are output along separate signal channels 330, 331 of SB 300 before being combined at crossover switch 350 (Figure 17b) to provide an uninterrupted stream of video image signals (analog video) for each line scanned. During this stage certain initial signal processing occurs. Inasmuch as the component parts of each signal channel 330, 331 are the same, only channel 330 is described in detail herein.

Operating clock signals ( $\phi_R$ ,  $\phi_{1-1}$ ,  $\phi_{1-2}$ ,  $\phi_{2-1}$ ,  $\phi_{2-2}$ ,  $\phi_{XA}$ ,  $\phi_{XB}$ , GOOD DATA, SAMPLE, AGC, STITCH) are derived from SEM 302. Time 0 is arbitrarily chosen as a time a particular array starts to clock out video image signals. It should be understood, however, that certain other events, principally scanning or integration, and charge transfer (where the image signals are transferred from photosensitive elements 311 to shift registers 320, 321), occur in the preceding cycle, i.e. from count 3462-3473 and count 3478-3489 (Figure 16b).

As described earlier, the viewing fields of arrays 40, 41 overlap one another to ensure an uninterrupted stream of video image signals. On clocking out of the image signals from shift registers 320, 321 crossover from one array (i.e. 40) to another (i.e. 41) is made at a preselected point within the overlapping viewing fields. The unused or excess image signals from both arrays 40, 41 are discarded.

All events are clocked from a master counter 406 (Figure 18, 19). With counter at zero, image signals in shift registers 320, 321 of array 40 are clocked out by clock pulses  $\phi_{1-1}$ ,  $\phi_{2-1}$  until a count of 1732 is reached. Clock pulses  $\phi_{1-2}$ ,  $\phi_{2-2}$  start at count 1716. At count 1724 the stitch signal (STITCH) goes low to trigger crossover switch 350 and couple array 41 to output lead 351.

With the crossover point selected in the example at count 1724, array 40 has 8 unused pixels (1724 - 1732) and array 41 has 8 unused pixels (1716 - 1724). These unused pixels are discarded.

Referring particularly to Figures 17a and 17b, video image signals output by the arrays are fed to emitter follower 333 which provides current gain and serves as a low impedance driver for sample and hold

circuit 339. Follower 333 may for example, comprise a Texas Instruments 3904 transistor. The signal output of follower 333 passes via lead 335 and blocking capacitor 336 to sample and hold circuit 339. Capacitor 336 serves to block out the relatively large DC offset of the arrays. A predetermined bias is provided by bias circuit 337.

Sample and hold circuit 339 may for example, comprise a Signetics SD 5000 circuit. (Circuit 339) responds to a periodic signal (SAMPLE) to periodically sample and hold the video image signals for a preset time interval. The output of sample and hold circuit 339 is fed via lead 340 to the non-inverting input of differential amplifier 341 which may for example, comprise a National Semiconductor LH 0032 amplifier. Amplifier 341 serves to modify the video image signal level in response to a gain signal (AGC) determined in accordance with the operating characteristics of each array by automatic gain control circuit 342, as will appear.

The image signal output by amplifier 341 is passed via lead 343 and blocking capacitor 344 to crossover switch 350 which as described couples one or the other array 40 or 41 to output amplifier 353 in response to a stitching signal (STITCH).

To restore channel 331 to a zero signal level prior to the next integration, a zero level restore (ZR) signal is input to switch 350 following the last image signal. In the exemplary arrangement shown in Figure 16, the ZR signal is input to switch 350 from count 3447 to 3462 to complete a circuit coupling crossover switch 350 to ground.

Referring particularly to Figure 18b, SEM 302 provides clock and timing signals for operating the various components of IIT 10. SEM 302 includes a clock pulse generator 400 which may for example, utilize a pair of crystals (50.31 MHz and 20.13 MHz) and a flip flop divider (not shown) for generating base multiple frequency clock pulses corresponding to different IIT scanning rates. As will appear, IIT 10 may be operated at one of several scanning rates which, in the example described, comprise rates of 2 mmps, 5 mmps and 125 mmps. Selection of the IIT operating mode by the user or operator through control panel 309 determines the scanning rate. A control signal (SPEED SELECT) corresponding to the scanning mode selected is input by MPU 308 to clock generator 400 of SEM 302 to select the output clock signal frequency of clock generator 400. SEM 302 is coupled to MPU 308 through

programmable peripheral interfaces (PPI) 405, which may for example, comprise Intel Model 8255A-5SR-PPI's.

The signal output ( $60R$ ) of clock pulse generator 400 is input to subclock generator 402. Subclock generator 402, which may comprise suitable flip flop based logic circuitry (not shown) divides the clock signals ( $60$ ) input by clock pulse generator 400 into operating clock signals  $0R$ ,  $20R$ , SHSMP (SAMPLE COMMAND) respectively. Clock signals  $0R$ ,  $20R$ , and SAMPLE COMMAND are input to IPM 304 and clock signal  $0R$  which is the reset signal corresponding to the pixel rate for arrays 40,41, is further input to master counter 406 of SB 300 (Fig. 19).

As described earlier, master counter 406 controls operational timing of arrays 40,41. Referring particularly to Figure 19, master counter 406 includes plural registers 437 responsive to clock signals  $0R$  from subclock generator 402 to provide a 12-bit clock signal output to bus 407 and count/decode logic 408. Bus 407 is also coupled to programmable pulse generator 416 and address circuit 421 of bad pixel RAM 420.

Count/decode logic 408 incorporates plural (i.e. 4) 6 bit to 8 bit registers with attendant NOR gate array (not shown) for decoding the clock signal input thereto from master counter 406 to provide a plurality of timed controlled signals to event timer 410. Event timer 410, which may comprise flip flop based logic (not shown) for subdividing the input pulses thereto, provides the enabling signal (GOOD DATA) and clock pulses  $0XA$ ,  $0XB$  to IPM 304 and clock pulses  $01-1$ ,  $02-1$ ,  $01-2$ ,  $02-2$ ,  $0XA$ ,  $0XB$  and sample signal (SAMPLE) to SB 302 as described heretofore in connection with Figure 16.

The function and purpose of programmable pulse generator 416 and bad pixel RAM 420 will appear hereinbelow.

The pulse clock frequency corresponding to 2 IPS (20.13 MHZ) generated by clock pulse generator 400 is output via lead 409 to A/D converter 501 of IPM 304 as will appear.

Video image signals (Analog Video) from SB 300 (see Figure 17) are input to IPM 304 for further processing prior to output to VOB 306 and/or MPU 308. Referring particularly to Figure 20, the flow of image signals through IPM 304 is there illustrated. A selector switch 500 permits the user to select the signal input source to be coupled to Sample and Hold

(S/H) circuit 501 from either SB 300 or from IIT test-calibration selector switch 502. Image signals from S/H circuit 501 are input to either threshold-screen processing section 505 or A/D conversion section 506 depending on the setting of selector switch 504 by the operator. Where PICTORIAL ENHANCEMENT MODE is selected, switch 504 is set to route image signals to A/D conversion section 506. Where LINE INPUT MODE or PICTORIAL INPUT MODE are selected, switch 504 is set to route the image signals to threshold-screen processing section 505.

Threshold-screen processing section 505 has selector switches 508, 509 for routing the image signals to either high speed (eg 125mmps) interpolator 510 (LINE INPUT MODE), or low speed (eg 50mmps) interpolator 512 (PICTORIAL INPUT MODE). The image signals from selector switch 509 are input to thresholder 514 where the signals may be either thresholded or screened, depending upon the output of screen-threshold circuit 516. D/A converter 517 converts the digital threshold-screen output of circuit 516 to analog signals for use by thresholder 514. The output of thresholder 514 which is in bit serial form, is routed either to VOB 306 or to serial-parallel converter 519. From converter 519, the signal output, in 8 bit form, is input to MPU 308.

Image signals routed to A/D processing section 506 are input to A/D converter 520 whereat the signals are converted from analog to 6 bit digital. The output of A/D converter 520 is fed to selector switch 522 which routes the signals to either VOB 304 or MPU 308.

To accommodate illumination vagaries and falloff of the exposure lamp, a shading compensation circuit 525 is provided. The output of circuit 525 is input via D/A converter 526 to both thresholder 514 and to A/D converter 520 for modifying the image data as will appear.

Referring particularly to Figures 21 and 22, S/H circuit 501 serves as both a low pass filter to remove noise from the image signals and to periodically sample and hold the image signal level sampled over a preset time interval. S/H circuit 501 may for example, comprise a Datel SHM-UH sample and hold circuit.

Video image data from SB 300 is input to S/H circuit 501 in lead 550 via selector switch 500. Sample and hold enabling signal (SHE) in lead 552 inhibits a sample command (SHSMP) if the A/D conversion by A/D converter 520 is not completed when operating in the PICTORIAL

ENHANCEMENT mode. Enabling signal SHE is derived from flip flop pair 801,802 (Figure 22) in response to the signal EADTB representing the operational timing of A/D converter 520 in the context of sample command clock signals SHSMP and DHSMP. Selection of this mode by the operator generates an enabling signal (A/D MODE) in lead 800 to flip flop 801. The sample command (SHSMP) signal in lead 553 is derived from subclock generator 402 of SEM 302 (Figure 18b) to operate flip flop pair 801,802 and activate S/H circuit 501 in timed synchronization with the input of video image signals such that each signal is sampled a predetermined distance between successive clock reset pulses. In the exemplary arrangement shown, samples are taken at  $5/6$  the distance between reset pulses. To correlate the sample command with the operating characteristics of S/H circuit 501, the sample command (SHSMP) signal is input to tapped digital delay 555 which for example, may comprise a Data Delay Model DDU-4. Digital delay 555 is set to delay the sample command signal for a preset interval to provide delayed sample command signal (DSHSMP). Both sample and delayed sample command signals (SHSMP, DSHSMP) are AND'd together in register 557 to provide a timed signal (SAMPLE COMMAND) to S/H circuit 501 through lead 558.

The sample command clock signals DSHSMP and SHSMP drive flip flops 801,802 to provide timed generation of sample and hold enabling signal (SHE).

Referring particularly to Figure 23, the image signals output by S/H circuit 501 are routed by selector switch 504 to lead 560 and A/D converter 520 (Figure 20) if PICTORIAL ENHANCEMENT MODE is selected or to lead 561 and selector switch 508 when either LINE INPUT MODE or PICTORIAL INPUT MODE is selected. Selector switch 508, in turn passes the signals to either lead 562 and high speed interpolator 510 (LINE INPUT MODE) or to lead 564 and low speed interpolator 512 (PICTORIAL INPUT MODE) in response to scan speed (SPEED) signal in lead 511. The scan speed signal it will be understood is dependent upon the operational MODE selected.

Interpolators 510,512 each comprise analog data delay lines 566,567. A linear interpolation filter is implemented by taking equally related subpixel taps 568, 569 over two adjacent pixels and summing the output to give a continuous analog signal which is later resampled by

sampler 590 (Figure 24) at a frequency double the pixel clock frequency to double the number of image signals (i.e. from 9 to 18 pixels per mm). An enhancement filter, which in the example shown is a 3 pixel-enhancement filter is also included. The filter is implemented using delay lines 566,567 and differential amplifiers 570,572. Amplifiers 570,572 weigh the combined signals of taps 568, 571, representing the outside pixel sum, with the sum of the center pixel taps 569. The outputs of differential amplifiers 570, 572 are selectively coupled to threshold 514 by selector switch 509 in response to the scan speed (SPEED) selected.

Data delay lines 566,567, which may for example, comprise Data Delay Devices No. 2214-4006 are identical except that delay line 567 for low speed interpolator 512 is longer than delay line 566 for high speed interpolator 519. Differential amplifiers 570, 572 may comprise RCA Model CA3100 OP AMPS.

Referring particularly to Figure 24, image signals output from processing section 505 are fed to analog signal comparator 575 of threshold 514 via lead 576. Comparator 575 which may comprise a Signetics NE 521 analog signal comparator, compares the image signals on a pixel by pixel basis with threshold-screen signals provided in lead 578. Where the level of the image signal is above the level of the threshold-screen signal in lead 578, a binary signal output of 1, representing a black image area, is generated in output lead 579. Where the image signal level is equal to or below that of the signal in lead 578, a binary output signal of 0 representing a white image area is generated.

Threshold-screen signals in lead 578 are provided by D/A converter 517 in response to a 6 bit fixed threshold or screen pattern input thereto from screen/threshold circuit 516 through lead 581. Referring particularly to Figure 25a, circuit 516 has screen values stored in RAM 741. The output of RAM 741 is coupled to control switch 745. Fixed threshold values are supplied by MPU 308 to threshold latch circuit 746. The output of latch 746 is coupled to control switch 745. A control signal (SELECT) from MPU 308 sets control switch 745 to output either screen values from RAM 741 or the fixed threshold value from threshold latch circuit 746 to lead 581 and D/A converter 517 in response to the operational mode selected, i.e. PICTORIAL or LINE INPUT MODE.

Bi-directional communication is provided between RAM 741 and MPU 308 through tri-state latch 740. During scanning, a local read

enable signal is input to multiplexer 742 through lead 739. Multiplexer 742 applies a read/enable signal to the  $\overline{WE}$  pin of RAM 741 and an output disable (DISABLE) signal to latch 740 through leads 738, 743 respectively. A second multiplexer 744 is addressed by column and row counters 748, 749 respectively driven by clock signals  $\phi_R$ ,  $\phi_L$  in synchronism with the pixel stream and scan line indexing respectively.

Scan line clock signals ( $\phi_L$ , LINE SYNC) are derived asynchronously from the main clock decoding circuitry of SEM 302. Because of the relationship, velocity of scan carriage 32 must be kept accurate and stable.

Column counter 748 addresses columns 0-7 and then self resets to effect reading of the thresholds along one scan line in blocks of 8 pixels at a time. Row counter 749 addresses the matrix rows comprising each scan line, i.e. during the first scan line the first row is addressed, during the second scan line, the second row, etc. Counter 749 repeats after each block of 8 scan lines.

Where a fixed threshold is called for (LINE INPUT MODE), the threshold is loaded by MPU 308 and latched. Control switch 745 is triggered to input the fixed threshold value output by latch circuit 746 to output lead 581. Counters 748, 749 are reset to zero count and inhibited.

In the MPU access mode, as for example, where new screen threshold values are to be written into RAM 741, MPU 308 sends a logic high signal through address line 714 and gate 747 to multiplexers 742, 744. The signal input switches multiplexers 742, 744 to select MPU control bus 716 and MPU address bus 714 instead of the local read enable signal in lead 739 and column/row counters 748, 749. MPU 308 thereafter applies through control bus 716 a logic high or logic low signal to multiplexer 742 to signal via  $\overline{WE}$  line 738 for MPU read or write respectively in RAM 741.

The binary image signals output by comparator 575 to lead 579 are fed to sampler 590 which may comprise a flip flop where the signals are sampled at a selected clock rate (XCLKM) to multiply the number of image signals. A stream of binary image signals from sampler 590 is output via lead 591 to VOB 306. Sampler 590 also controls the size of the output image as will appear.

Referring to Figure 26, image signals from comparator 575 are also input to video register pairs 592, 593 of serial-parallel converter 519 where the binary image signals are converted to parallel 8 bit image data.

Image data from converter 519 are output through bus 597 to MPU 308 in response to a read signal (RDVR) from MPU 308.

Image signals output by sample and hold circuit 501 may be routed by selector switch 504 to lead 560 and A/D converter 520 when PICTORIAL ENHANCEMENT MODE is selected by the operator. Referring particularly to Figures 27-29 and 22, A/D converter 520, which may comprise a TRW Model TDC-100UA/D converter, serves to convert the analog image signals into 8 bits of digital information. Where the image data are output to VOB 306, the least two significant bits are dropped to provide a 6 bit output to VOB 306. Data output to MPU 308, normally for calibration or diagnostic purposes, is in 8 bit form. Image data output to either VOB 306 or MPU 308 is selected by switch 522. Switch 522 comprises A/D register pair 595 to which the image data from A/D converter 520 are output. Image data from A/D register pair 595 are output to VOB 306, and to MPU register pair 597. On a read signal (RDDR) from MPU 308, MPU register pair 597 provide single byte image data to MPU 308. Image data from video register pairs 592, 593 (See Figure 26) and from MPU register pair 597 are input to MPU for calibration, diagnostic, etc. purposes.

Referring particularly to Figures 22, 27, and 29 A/D converter 520 is enabled by a start A/D conversion signal (STCNN) responsive to establishment of the A/D time base (STADTB) and clocked at the low speed clock signal (20 MHz) derived from output lead 409 of clock generator 400 (Figure 18b). Clock driving pulses (A/D CLK) for A/D converter 520 are similarly derived from the low speed clock signal output of generator 400 in response to an A/D Mode input Signal from MPU 308.

Inasmuch as the operational speed of A/D converter 520 is limited, only image pixels up to a predetermined maximum pixel rate (eg 25 mmps) can be converted by A/D converter 520. Where the input pixel rate is above the predetermined maximum rate, only selected pixels of each scan line may be converted.

Referring to Figure 30, MPU 308 controls the sequence of events in IIT 10 in accordance with a predetermined software program. MPU 308 includes a suitable CPU chip 700 such as an Intel Model 8085 CPU chip manufactured and sold by Intel Corporation, DMA controller 702, ROM memory 704, RAM memory 706, and interrupt controller 708. Crystal

oscillator 710 provides clock signals for MPU 308 and for the Y scan servo loop speed reference (SPEED) of SEM 302. See Figure 18a. Operating control software resides partially in ROM 704 with the remainder softloaded into RAM 706.

MPU 308 is interfaced with the various operating components that comprise IIT 10 via SEM module 302, and with IPM module 304 via IPM interface 721 through 8 bit bidirectional data bus 712, 16 bit address bus 714, and control bus 716. Suitable bus drivers 717 are provided.

Interrupt controller 708 serves to permit a routine in progress to be interrupted, and to preserve the environment of the interrupted routine with return to the point of interruption. Interrupt controller 708 also permits IIT 10 to be coupled with other apparatus (for example, data storage facilities, copy printer, etc.), the interrupt serving to control a DMA channel allocated for data and/or command transfers between IIT 10 and such other apparatus, to verify data received, and to interrupt and perform such data/unload commands, flags, etc. as may be required.

A second interrupt source, real time clock (RTC) software module 718 includes procedures for updating a 32 bit counter 719 at each interrupt, for computing the end time of an event by adding the count of counter 719 to a user specified value, comparing the RTC counter with a user specified time, and reading counter 719.

System control over IIT 10 is exercised by a software scheduler having procedures for initializing, scheduling, and transmitting various operational tasks or programs. Tasks which communicate with one another through system control tables are scheduled by calling a scheduler procedure and identifying appropriately the task to be scheduled. IIT 10 is controlled by entering commands at the operator's console or panel 309, or by commands from other associated units via a direct memory access (DMA) channel allocated therefor. Commands entered are interpreted and processed.

Operational control programs for IIT 10 include monitoring operator panel 309, operating scanner section 12 and document handler 14, analyzing instructions received, calibration, and system initialization. Additional software programs have control procedures for individual component initialization and verification, for loading and verifying halftone screen RAM 741, for shading, for MPU initialization and self test, and for bad pixel deletion.

Referring to Figure 25b, IPM interface 721 includes address decoder 724 for decoding address data input thereto through address bus 714, the output of decoder 724 being input to AND gates 726, 727, and 747. Control signals from MPU control bus 716 are input to a second input of gates 726, 727. The output of gates 726, 727 regulate enablement of scale coefficient latch 731 and mode control latch 732 respectively. When triggered, the signal output of scale coefficient latch 731 sets the programmable multiplier of Binary Rate Multipliers (BRM's herein) 750, 751 (Figure 31) for the image pixel resolution and magnification selected by the user. Mode control latch 732, when triggered, provides the signal (AD mode) identifying the operational mode of IIT 10.

Referring particularly to Figures 20 and 31, the signal outputs of scale coefficient latch 731 controls the setting of BRM's 750, 751 which in turn control both the image resolution, i.e. the number of pixels in each line and the number of lines and, therefore the image size. BRM 750, which controls the number of pixels in each scan line (i.e. the X dimension) has a clock signal  $\phi$  from SEM 302 corresponding to the maximum pixel rate per line input thereto. The output signal of BRM 750 (XCLKM) is input to sampler 590.

BRM 751, which controls the number of lines scanned (i.e. the Y dimension), has line clock signals (LINE SYNC), representing the maximum number of lines to be scanned, input thereto. The signal output of BRM 751 (GATED LINE SYNC) is input to X-scan boundary control 753 (Figure 35).

It will be understood that BRM's 750, 751 which may for example, comprise Texas Instrument's model 7497 BRM's each incorporate a programmable multiplier enabling a selected output frequency, which is a factor of the input frequency, to be obtained, depending upon the control signal input. To provide the selected output frequency, BRM's 750, 751 drop selective clock cycles from the input clock frequency.

To accomplish both X and Y dimension scaling, the nearest neighbor algorithm is applied. By applying an input CLK with frequency  $\phi$  to a BRM, the output clock frequency  $\phi_s$  is given by:

$$\phi_s = \frac{M \cdot \phi}{64} \text{ where } 0 \leq M \leq 63 \text{ i.e. 6 bits binary coded decimal.}$$

If two devices are cascaded, the output frequency is then:

$$f_s = \frac{M_1 \cdot f}{64} + \frac{M_2 \cdot f}{4096}$$

To realize the output clock frequency  $f_s$ , selected clock cycles of the input clock  $f$  are dropped in a manner identical to the nearest neighbor algorithm. Figure 34 illustrates an exemplary relationship between input and output clocks for an  $M_1 = 48$  and  $M_2 = 0$ . This results in an output clock frequency of  $f_s = 0.75f$ .

Applying the line sync clock to the input of BRM 751, the output clock (GATED LINE SYNC) will have selected cycles deleted. Gating the binary video output with this clock will, therefore, remove selected lines according to the programmed multiplier  $M_1$  and  $M_2$ . In the example shown, every fourth line is deleted.

Applying a clock frequency of  $2f$  to the X-dimension BRM 750, the output clock (XCLKM) will be the required clock, scaled from  $2f$  for both X-dimension interpolation and image scaling. In the example shown, every fourth pixel is deleted.

Referring to Fig. 35, VOB 306 contains the image signal and line sync signal formatting functions in the form of differential pulse-code modulator (DPCM) 754, serial to parallel binary video formatter 755, line sync signal and scan boundary control 753, and DPCM data formatting and 9-wire output interface 756.

DPCM 754 serves to compress the 6 bit digital data input from A/D converter 520 to 4 bits with subjectively inconspicuous error to provide a bit rate that corresponds with the speed limits of typical data storage devices. In addition, formatting the data in 4 bit nibbles simplifies transmission and further compression. The algorithm applied to accomplish DPCM is to compute a difference value  $d_n$ .

$$d_n = X_n - X_{n-1} - e_{n-1}$$

where  $X_n$  = present video sample value;

$X_{n-1}$  = previous video sample value;

$e_{n-1}$  = previous error in quantizing the value  $d_{n-1}$ ; and

$$e_n = q_n - d_n$$

The difference value  $d_n$  is then quantized to a value  $q_n$  according to a preset mapping table. An exemplary mapping table is shown in Table I. Referring thereto, mapping is effected by mapping from the

value  $d_n$  in the first column (Difference) to the corresponding value  $q_n$  in the third column (Quantization). The quantized difference value  $q_n$  is mapped to a 4 bit nibble using the corresponding 4 bit  $M_n$  in 4th column (4 bit code). As seen in Table I, the difference values  $d_n$  with magnitudes larger than 32 are coded to the same  $q_n$  values for both positive and negative values of  $d_n$  to use the 4 bit codes more efficiently. Later decoding employs the equation  $X_n = X_{n-1} + q_n$ .

For the values of  $q_n$  larger in magnitude than 32, adding the incorrect sign  $q_n$  to  $X_{n-1}$  will result either in a negative  $X_n$  or in a larger than scale ( $> 64$ ) positive  $X_n$  which are both physically incorrect. In this case both the positive and negative values of  $q_n$  are added to  $X_{n-1}$  and the value of  $X_n$  that is positive and within the range (64) is chosen as the output for  $X_n$ . Both encoding and decoding algorithms presume initial zeros i.e.  $X_{n-1}$  and  $e_{n-1}$  are initially zero for encoding and  $X_{n-1}$  is zero for decoding respectively. The following example illustrates the algorithms.

Assume input samples are  $X_0 = 10$ ,  $X_1 = 54$  and  $X_2 = 12$ .

Encoding:  $d_0 = 10 - 0 = 10$ ,  $q_0 = 11$ ,  $e_0 = 1$ ,  $M_0 = 0100$

$d_1 = 54 - 10 - 1 = 43$ ,  $q_1 = 47$ ,  $e_1 = 4$ ,  $M_1 = 1110$

$d_2 = 12 - 54 - 4 = -46$ ,  $q_2 = 47$ ,  $e_2 = -1$ ,  $M_2 = 1110$

Decoding:  $M_0 = 0100$ ,  $q_0 = 11$ ,  $X_0 = 11 + 0 = 11$

$M_1 = 1110$ ,  $q_1 = \pm 47$ ,  $X_1 = 11 + 47 = 58$

$X_1 = 58$  (positive  $\leq 64$ )

or  $X_1 = 11 - 47 = -36$

$M_2 = 1110$ ,  $q_2 = \pm 47$ ,  $X_2 = 58 + 47 = 105$

(105 is  $> 64$ ) or  $X_2 = 58 - 47 = 11$ .

Thresholder 514, in LINE or PICTORIAL INPUT MODES provides 1 bit/pixel output. This data is formatted to 4 bit nibbles by formatter 755 which may comprise plural serial-to-parallel registers. Pixel clock  $\phi$  is input to formatter 755 and similarly divided by 4. Both the formatted image and clock signals are output to interface 756.

Line Sync Signal and X-Scan Boundary Control 753 serves to delay the line sync signal 757 input to control 753 to provide a Delayed Line Sync Signal 758 delayed by a period equal to all the delays encountered in the video path i.e., from filtering, sampling, thresholding DPCM, etc. in each mode of operation. The delayed line sync signal 758, which synchronizes the output with valid data, is also used to determine the scan

boundary in the X-dimension. This is accomplished by dropping the line sync signal 758 to logic zero at the actual end of a scan line. Scan boundary in the Y-dimension is determined by SEM 302 and the output.

Additionally, control 753 generates a switching signal 759 that divides the scan line output of DPCM 754 into two parts. This last function is applied only in the PICTORIAL ENHANCEMENT MODE.

For this purpose, each line of DPCM data (a scan line) is formatted into two equal parts using first-in-first out (FIFO) buffer 760 and switch 761. The first half line is made equal to one half the scan line (in number of pixels), after which the line sync signal is dropped to logic 0 for a period of time equal to a few pixels. The line sync signal is then raised back to logic 1 indicating the start of the next half line. On dropping of the line sync signal to logic 0, the output of DPCM 754 is coupled to buffer 760 by switch 761. Buffer 760 delays the image data comprising the one half line by a period equal to the period during which the line sync signal dropped to logic zero, avoiding any loss of image data. By dividing the scan line into two equal parts, the number of bits per line is kept within the limit acceptable to the output.

For example, if the maximum number of pixels/line is 3440, X-dimension interpolation by interpolator 510 or 512 doubles the number of pixels to 6880 pixels/line. The output, therefore is binary video (i.e., 1 bit/pixel) totaling 6880 bits/line.

In the PICTORIAL ENHANCEMENT mode, which uses DPCM 754, the number of pixels output is equal to the number of pixels scanned, i.e., 3440 per line. Since DPCM 754 provides 4 bits/pixel, the number of bits/scan line output by the DPCM is 13760 bits/line, which is double the number for the other operational modes. By dividing the scan line into two parts in this mode (PICTORIAL ENHANCEMENT MODE) each line part contains the same number of bits as a scan line in the other modes (LINE INPUT and PICTORIAL INPUT MODES).

TABLE I  
DPCM LOOK-UP (6 - 4 bits)

Where the image signals output by IIT 10 exceeds the capability of the output device (as for example a storage disk) to assimilate the image signals, a suitable overload signal (not shown) indicating overload of the output device input sets IIT 10 into DEFAULT MODE. In this mode, a control signal from MPU 308 returns scan carriage 32 to home position to initiate a new scan at relatively slower speed. In the exemplary arrangement shown, scan carriage 32 is operated at a speed of 50mm/ps in the DEFAULT MODE with arrays 40,41 operated at 25mm/ps. Effectively, this results in arrays 40,41 scanning every other line to provide an output image resolution of 9 lines per mm by 9 pixels per mm.

#### CONTROLS

Control over scanning operation of IIT 10 and document handler 14 is exercised by MPU 308 in accordance with instructions from the user or operator through control panel 309. Referring to Figure 18a, document handler 14 incorporates a cover interlock switch 780 for generating a document handler enabling signal when cover 24 thereof is closed. Where documents are to be manually fed, cover 24 of document handler 14 is raised (as shown in Figure 11) opening interlock switch 780 and disabling document handler 14.

One or more document presence switches 782 are disposed adjacent document feed slot 210 and document handler 14 to detect insertion of a document to be fed therein. As described heretofore, documents to be fed are manually inserted into slot 210 following which document handler 14 advances the document into registered position on platen 28. In addition, one or more document jam switches (not shown) may be disposed at convenient places along the document path.

Operating control data from MPU 308 are distributed to motor 290, solenoids 225,260, and clutch 291 of document handler 14, and to exposure lamp 65 of IIT 10 through buffer 784. Buffer 784 is loaded with control data from MPU 308 through data bus 712 such that when a document has been inserted into feed slot 210 of document handler 14, solenoid 225 is actuated to drop fingers 216, start motor 290 and engage clutch 291. Motor 290 drives rollers 201, 202 and feed belt 230 to advance the document into registered position on platen 28. Following registration of the document, scan motor 39 is energized to move scan carriage 32 and scan the document. On completion of the scanning cycle, a signal from MPU 308 actuates

solenoid 260 to drop registration gate 29, start motor 290 and engage clutch 291 to operate feed belt 230 and exit rollers 265, 266 to remove the document from platen 28 and into output tray 267.

Referring particularly to Figures 18a and 36, an encoder 786 is provided on the output shaft of scan carriage motor 39. Encoder 786 generates quadrature, i.e.  $90^\circ$ , out of phase signals in lead 787 reflecting rotation of motor 39 in either a forward or reverse direction. Direction detector 788 uses the  $90^\circ$  phase relationship of the input signals from encoder 786 to determine the direction of rotation of motor 39 and hence the direction of movement of carriage 32, detector 788 providing either forward (FOR) or reverse (REV) control pulses to forward (SCAN) and reverse (RETURN) position counters 806, 808 respectively. Forward (FOR) and reverse (REV) position counters 806, 808 count down from a home position in preset increments (eg 39 counts per mm of travel of scan carriage 32) from a maximum count, counters 806, 808 being set to the maximum count at the carriage home position. To determine carriage home position, motor 39 is energized in the reverse (REV) direction to move carriage 32 backwards until the carriage abuts a carriage bumper (not shown). Counters 806, 808 are then zeroed and set to the predetermined maximum count. As will be understood, the count on counters 806, 808 reflects the position of carriage 32 which may be determined at any point during scan by subtracting the count on forward counter 806 from the count on reverse counter 808.

Programmable frequency generator 790 generates a frequency signal (REF) which is input via lead 791 and multiplexer 793 to phase detector 792 of phase lock loop 795 for phase locked motor operation. Multiplexer 793 is controlled by signals (DIRECTION) from MPU 308 multiplexer 793, during scan, coupling the forward (FOR) control pulses of direction detector 788 together with the forward reference signal (REF) to phase detector 792, and during carriage return, coupling the reverse (REV) control pulses of detector 788 together with the reverse reference signal (REF) to phase detector 788. As will appear, phase detector 792 compares the frequencies of forward (FOR) and reverse (REV) control pulses with the reference signal (REF) input by frequency generator 790. The frequency of the reference signal (REF) output by generator 790 is set by control signal from MPU 308 in response to the operational mode selected by the user.

Generator 790 also serves as a variable duty cycle generator for open loop driver 794 (Figure 18a).

Control over scan carriage motor 39 is exercised through phase locked loop section 795; the output of phase detector 792 thereof being input to adder 797 which sums the outputs of phase detector 792 in accordance with a predetermined formula. The signal output of adder 797 is input via loop filter 796 to power amplifier 798 controlling power input to motor 39. Loop filter 796 comprises a low pass active filter with predetermined gain (i.e. 2.5); filter 796 being tuned to roll off at 100 cycles to filter out transients.

In operation, a signal (DIRECTION) from MPU 308 sets multiplexer 793 in accordance with the direction in which scan carriage 32 is to move, i.e., in the forward (SCAN) direction. MPU 308 loads a succession of different frequency selecting signals, into frequency generator 790. Generator 790 responds by outputting to phase comparator 792 reference signals (REF) at the frequencies selected. For startup purposes, the first reference signal frequency is relatively low (eg 1kHz) with subsequent reference signals being increased stepwise in frequency. As the speed of scan carriage 32 approaches the operating speed desired, the frequency steps are reduced from relatively large (coarse) steps to relatively small (fine) steps.

Phase detector 792 compares the frequency of the reference signal (REF) from frequency generator 790 with the frequency of the signal representing the speed at which scan carriage 32 moves as determined by shaft encoder 786. Where a difference exists, an error signal is generated.

The error signal is input through filter/amplifier 796 to power amplifier 798 to energize carriage drive motor 39. Motor 39 accelerates carriage 32 in the desired direction. The increase in the speed of carriage 32 in turn increases the frequency of the signal output by shaft encoder 786 until the frequency of the reference signal (REF) and the frequency of the signal from shaft encoder 786 match, at which point the error signal output by phase comparator 792 falls to zero, interrupting power to motor 39.

The above procedure is repeated periodically (i.e. in intervals of 0.001 seconds) until scan carriage 32 reaches the desired operating speed. Thus, as scan carriage 32 accelerates, MPU 308 periodically steps up the frequency of the signal output by generator 790. Phase lock loop 795

responds to energize carriage drive motor 39 and accelerate carriage until the carriage has been stepped through the speed plateaux represented by each successive reference signal to the final predetermined carriage speed.

It will be understood that the final carriage speed in the scan direction is dependent upon the operating mode selected as described heretofore. The return (RETURN) speed of scan carriage 32 is the same in all operating modes.

With scan carriage 32 at desired operating speed, and frequency of the reference signal output by frequency generator 795 constant, phase lock loop 795 serves to maintain carriage 32 at the desired operating speed. Should scan carriage 32 slow, phase detector 792 detects the change in frequency between the signal output of shaft encoder 786 and the reference signal output by generator 790 and generates an error signal energizing motor 39.

As scan carriage 32 approaches the End of Scan (EOS), a signal from MPU 308 closes switch 799 to short out filter/amplifier 796 thereby providing a gain of zero. With gain set to zero, power to carriage motor is interrupted, stopping scan carriage 32.

Phase comparator 792 may comprise a Motorola MC 40 Phase Frequency Comparator which generates an output proportional to the phase or frequency difference between the encoder signal and the reference signal (REF) input by generator 790 while shaft encoder 787 may comprise Model 992-500 OCLP manufactured by Disc Instruments. Counters 806, 808 may comprise Intel 8253 16 bit down counters while adder 797 may comprise a 741 Differential Amplifier. Programmable frequency generator 795 preferably consists of a crystal clock and programmable counters.

When it is desired to operate scan motor 39 in an open loop fashion as for example during calibration, a signal in lead 801 activates multiplexer 800 to switch from the output of phase lock loop section 795 to the output of open loop driver 794. The speed and direction of movement are controlled by a signal from MPU 308 via lead 803. Forward and reverse counters 806, 808 permit MPU to monitor the position of scan carriage 32 as described earlier.

Referring to Figure 2, a reflective calibration strip 900 of predetermined reflectivity is mounted on platen 28 on the underside thereof along the platen leading edge. Disposition of calibration strip 900 on the underside of platen 28 provides a defocused image for arrays 40,41 and reduces interference of dust, dirt, scratches and other defects that may occur on the video calibration signal generated by arrays 40,41. Preferably the reflectivity of strip 900 is chosen to provide an optical signal equivalent to a 50 percent reflective document placed on platen 28.

The video calibration signals obtained from reading calibration strip 900 may be taken from either video output registers 593 of screen/threshold section 505 (Figure 26) when calibrating IIT 10 for LINE INPUT and PICTORIAL INPUT MODES, or from video output registers 596 of AD section 506 (Figure 28) when calibrating IIT 10 for PICTORIAL ENHANCEMENT MODE. It will be understood that the particular MODE calibrated is dependent upon the MODE selected by the operator. The video calibration signals are input to MPU 308 for processing.

Additionally, calibration video, which may be either fixed level video from MPU 308 or video calibration signals from VOB 306, may be introduced into IIT 10 to verify operation of IPM 504. Referring particularly to Figure 20, selector switches 500,502 are preset by the user or operator to couple either MPU 308 or VOB 306 to sample and hold circuit 501 of IPM 504. The calibration video introduced into IPM 504 from either MPU 308 or VOB 306 is passed through digital-to-analog (D/A) converter 503 to convert the video signals from digital to analog.

In order to correlate the image output levels of arrays 40,41 with one another, automatic gain control (AGC) is provided. The amount of gain required is determined by comparing the voltage output of arrays 40,41 when reading calibration strip 900 with a desired level or threshold value.

At startup before scan is initiated, scan carriage 32 is brought to the position where arrays 40,41 are disposed below calibration strip 900. Movement of carriage 32 into position where arrays 40,41 are opposite strip 900 is effected by the operator through suitable carriage forward (FOR) and reverse (REV) controls (not shown) on operator control panel 309 or automatically under program control. MPU 308 responds to produce the

appropriate carriage forward or reverse signal (DIRECTION) to open load driver 794 (Figure 18b) to energize scan carriage drive motor 39 and move carriage 32 in the direction desired.

With arrays 40,41 disposed below calibration strip 900, strip 900 is scanned a plurality of times in each operational mode. As will be understood from the previous description, the video signals generated by arrays 40,41 pass through amplifiers 341 in signal channels 340,341 through crossover switch 350 of SB 300 (Figures 17a, 17b). From SB 300, the video signals pass to IPM 304 and either A/D conversion section 506 and A registers 596 (Figure 28), or to high speed interpolator 510 or low speed interpolator 512 (Figure 20) and output registers 593 (Figure 26) depending on the operational mode selected. From registers 596,593, the image signals may be input to MPU 308 in response to register read signals RDDR and RDVR.

The data derived from each array 40,41 are iteratively adjusted to obtain the optimum gain value for each array for each operational mode in accordance with a suitable program. In a preferred program, the outputs of D/A converters 912, 913 (Figure 32) to amplifiers 341 of signal channels 340,341 is initially stepped up in relatively large increments (i.e. in blocks of 16) until the desired signal output gain is attained. Normally however, because of the coarse nature of the steps, the signal output of the amplifiers 912 or 913 associated with the array 40 or 41 whose gain is being set, will exceed the signal output gain desired. The converter 912 or 913 is then stepped down in smaller increments (i.e. in blocks of 4) until the signal output gain equals or re-crosses the signal output level desired. The above described process continues with smaller and smaller increments until the signal output gain of the amplifier 912 or 913 for each array 40 or 41 equals the signal output gain desired.

The above process is carried out for each array 40,41 for each operational mode and the gain settings derived are stored in RAM 706 (Figure 30) for use during subsequent scanning operations.

In a preferred arrangement, the gain is determined by monitoring the signal output of the last four photosensitive elements before crossover of array 40 and the first four photosensitive elements after crossover of array 41. It will, however, be understood that other photosensitive elements or other groups of photosensitive elements may instead be used for this purpose.

Referring to Figure 18b, AGC pulse generator 416 is driven by the clock pulse output of pixel counter 406. As described, counter 406 provides clock pulses for clocking out image pixels from arrays 40,41. MPU 308 generates at the desired pixel count, an enabling signal activating pulse generator 416. The signal output pulses of generator 416 (RDVR; RDDR) enables video output registers 593 (Figure 26) or 596 (Figure 28) respectively to input image data from registers 593 or 596 to MPU 308, depending upon the operational mode selected.

In the example alluded to heretofore (Figure 17), where crossover from array 40 to array 41 takes place at pixel count 1724, MPU 308 actuates AGC pulse generator 416 at pixel count 1720 through 1728, to transfer image pixels from the last four photosensitive elements of array 40 together with the first four photosensitive elements of array 41 to MPU 308.

MPU 308 averages the block of image pixels from each array and compares the averaged signals with a predetermined signal or threshold level. A gain signal representing the difference between the calibration image pixels and the predetermined signal level is produced for each array.

Referring to Figure 32, the gain signal from MPU 308 is input to D/A converters 912,913 for arrays 40,41 respectively. D/A converters 912,913 convert the digital gain signal output by MPU 308 to an analog signal which is input via leads 915,916 respectively to amplifiers 341 of the signal processing channels 330,331 associated therewith (Figure 17b). The gain signal serves to regulate the amplitude ratio or gain of amplifiers 341 to provide a uniform image signal level from each array.

On each scan, arrays 40,41 scan across calibration strip 900 to provide updated gain control information to MPU 308 prior to scanning the document 8 on platen 28. The updated calibration signals generated by the last four photosensitive elements of array 40 and the first four photosensitive elements of array 41 are input to MPU 308 where, as described, the calibration signals from each array are averaged to provide an updated gain signal for each array 40,41. The updated gain signals are input to RAM 706 to update the existing gain signals stored therein.

Because scan carriage 32 is moving relative to calibration strip 900 when updating of the gain control signals is taking place, the interval within which corrections in gain level can be made is limited. This in turn restricts the number of adjustments in gain level that can be made per

array. In the exemplary arrangement shown, the interval is such that only changes in gain setting of one step can be made. However, as long as any drift or change in array performance is relatively minor, the aforesaid updating will maintain the desired array operating level. If a substantial change in array performance takes place, several scans may be required before the desired gain level is restored.

The image data obtained from scanning calibration strip 900 are also employed to compensate the video image output signals of arrays 40,41 for illumination system profile irregularities such as may be caused by cosine 4th law, profile of scanning lamp 65, vignetting, etc. Referring particularly to Figure 33, the aforesaid compensation, termed Shading herein, takes image pixels produced by scanning calibration strip 900 from A/D video register 595 in blocks of predetermined size (i.e. 16) and inputs the pixels to adder/divider circuit 925 which provides an average pixel value representative of the pixel block. The averaged pixels or shading signals are stored in Shading RAM 926 for later use on a write signal from MPU 308.

During operation, the contents of Shading RAM 926 are cyclically addressed by address counter 421, which is enabled at the start of scan (START LINE) to sequentially address the shading signals held therein. Counter 421 is driven in synchronism with the stream of image pixels by pixel clock  $\phi$ . A read signal (READ) from MPU 308 enables RAM 926 for this purpose.

The shading signals from shading RAM 926 are input to D/A converter 928 (Figure 24) which converts the digital shading signals to analog signals. The output of D/A converter 928 is input via lead 929 to D/A converter 517 of thresholder 514 (shown in Figure 24) where the shading signals are, in effect, multiplied by the analog threshold/screen signals output by converter 517, and via lead 930 to A/D converter 520 (shown in Figure 27) of A/D section 506 where the shading signals are, in effect, multiplied by the input image signals.

To accommodate differences between A/D converter 520 and thresholder 514, a proportionality constant is introduced in the shading signals output by D/A converter 928. For this purpose, attenuating circuits 940,941, which comprise suitable resistor networks are disposed in leads 930,929 respectively. Attenuating circuits 940,941 serve to multiply the

shading signal output by D/A converter 928 by a preselected proportionality constant.

Where desired, i.e. for test purposes, a source 931 of digital shading signals may be provided with manually controlled selector switch 932 for selectively coupling shading signal source 931 with D/A converter 928.

As can be understood, certain photosensitive elements 312 in the multitude of photosensitive elements that comprise arrays 40,41 may be or become inoperable or below par. In this situation, the image signal output by the affected photosensitive element or elements may be faulty, or have sensitivity characteristics significantly different from the image signals output by neighboring photosensitive elements. To identify and accomodate bad or faulty photosensitive elements, a bad pixel deletion control is provided. As described, SEM 302 (Figure 18b) supplies a control signal (SAMPLE) to sample and hold circuit 339 on SB 300. Referring to Figure 17b, in normal operation, one sample signal is generated for each video image signal and triggers sample and hold circuit 339 which samples and holds the video image signal input thereto for a preset time interval in output lead 340. Capacitor 345, which is coupled to output lead 340, charges each time to a voltage level corresponding to that of a sampled video image signal.

The bad pixel deletion control interrupts input of the control signal (SAMPLE) to sample and hold circuit 339 to prevent circuit 339 from sampling the next video image signal. In this condition, the previous video image signal output by sample and hold circuit 339, which is held on capacitor 345, forms the video image signal output to differential amplifier 341.

To identify bad or faulty elements, calibrating strip 900 is scanned in each of the LINE INPUT, PICTORIAL INPUT, and PICTORIAL ENHANCEMENT MODES, and the image data output to MPU 308. MPU 308 compares the image signal output of each photosensitive element of arrays 40,41 with a predetermined minimum voltage level or threshold. Where the image signal is above the minimum threshold value, and hence acceptable, a binary signal (i.e. 1) is loaded into bad pixel RAM 420 (Figure 18b) by MPU 308. Where the image signal is below the minimum threshold value and

-37-

hence unacceptable, a binary signal (i.e. 0) is loaded into RAM 420. In the calibration mode, MPU 308 generates a write (WRITE) signal enabling data to be loaded into RAM 420.

During scanning operation, a read signal (READ) from MPU 308 enables reading of the data stored in RAM 420. Address counter 421 which is driven by pixel clock signals from pixel counter 406 and is reset at the start of scan of each line by a signal (START LINE) from MPU 308, sequentially addresses RAM 420 and the control data therein. The output of RAM 420 is input through lead 422 to AND gate 423. A sample signal is periodically generated by event timer 410 and input to gate 423 through lead 424. The output of gate 423 (SAMPLE) is input to sample and hold circuit 339 through lead 425.

Where the signal input from Bad Pixel RAM 420 is high (i.e. 1), AND gate 423 is enabled and on a pixel clock signal  $\phi$ , gate 423 is triggered to generate a sample (SAMPLE) signal in lead 425 to SB 300. As described, the sample (SAMPLE) signal triggers S/H circuit 339 to sample the next video image signal.

Where the signal input from Bad Pixel RAM 420 is low (i.e. 0) indicating a "bad" photosensitive element, gate 423 remains in a blocking condition to prevent output of a sample (SAMPLE) signal. As a result, the previous image signal, which is retained by capacitor 345, is output.

CLAIMS:

1. Apparatus for compensating a raster scanner for component deficiencies, the scanner having a platen (28) for supporting image bearing originals for scanning, at least one array (40) for line scanning an original (8) on said platen comprised of a plurality of photosensors and producing analog image signals representative of the image area scanned, and analog-to-digital converting means (520) for converting said analog image signals to digital image signals, characterized by:

a) a calibration image (900), scanning of said calibration image by said array producing analog calibration signals;

b) means for feeding said analog calibration signals to said analog-to-digital converting means; said analog-to-digital converting means converting said analog calibration signals to digital calibration signals;

c) means (925) for averaging groups of said digital calibration signals, each of said groups comprising digital calibration signals from a preset number of said array photosensors;

d) digital-to-analog conversion means (928) for converting the averaged calibration signals to analog signals; and

e) compensating means (514, 520) for compensating the image signals produced by said array with said averaged calibration signals.

2. The apparatus according to claim 1, characterized by memory means (926) for storing said averaged calibration signals for use in compensating image signals produced by said array; and

address means (421) for addressing said memory means during scanning to provide said averaged calibration signals for compensating said image signals.

3. The apparatus according to claim 1 or 2 characterised in that said compensating means includes means to input said averaged calibration signals to said analog-to-digital conversion means (520) during scanning of original images, said averaged calibration signals biasing said analog-to-digital conversion means to modify image signals input to said analog-to-digital conversion means from said array.

-2-

4. The apparatus according to claim 1, characterized by thresholder means (514) for processing said analog image signals produced by said array to provide binary image signals,

selector means (504) for routing said analog image signals produced by said array to said analog-to-digital conversion means to provide digital image signals and to said thresholder means to provide binary image signals selectively, and

means (929, 930) for inputting said averaged calibration signals to said analog-to-digital conversion means and said thresholder means to modify image signals input to said analog-to-digital conversion means and to said thresholder means.

5. The apparatus according to claim 4, characterised in that said thresholder means includes a screen (741) for screening said image signals and a thresholder (746) for thresholding said image signals, and second selector means (745) to route said image signals to one of said screen and thresholder selectively.

6. The apparatus according to claim 4 or 5 characterised in that said thresholder means includes a second digital-to-analog conversion means (517) for converting digital threshold signals to analog threshold signals, said averaged calibration signals being input (929) to said second analog-to-digital conversion means to bias said second analog-to-digital conversion means and modify the threshold level output of said second analog-to-digital conversion means; and

proportionality means (940, 941) for correlating the average calibration signals input to the first and second analog-to-digital conversion means with the operating characteristics of said first and second analog-to-digital conversion means.

7. The apparatus according to any preceding claim, characterised in that said calibration image is out of focus relative to said array whereby to reduce uniformity problems.

8. The apparatus according to any preceding claim, characterised in that said calibration image is disposed on the underside of said platen.

9. The apparatus according to any preceding claim characterised by:  
readout means (339) for reading out image signals from said array in succession to an output line, and  
control means (423) for causing said readout means to skip readout of faulty viewing elements in said array.

10. The raster scanner according to claim 9, characterised in that said control means includes means (345) to substitute the image signal from an adjoining viewing element for any viewing element skipped by said readout means.

11. The apparatus according to claim 9 or 10, characterised by:  
image signal storage means for temporarily holding previous image signals for substitute use.

12. A method of compensating a raster scanner for component deficiencies consisting of variations in light to which individual image sensors of a scanning array are subjected, characterized by the steps of:

- a) producing a separate test signal from each sensor in said array by scanning a test image of predetermined optical density;
- b) segregating said sensors into groups each comprised of a preset number of sensors;
- c) averaging the test signals from each of the sensors in said sensor groups to provide composite compensating signals for each of said sensor groups;
- d) storing said compensating signals; and
- e) correcting the signal output of each sensor with the stored compensating signal for the sensor group within which said sensor is included.

13. The method according to claim 12 characterised by the steps of:

- a) processing image signals output by said sensors when scanning original images to provide multi-bit digital signals representative of the image gray level in a first operating mode;
- b) processing image signals output by said sensors when scanning original images to provide single bit binary level signals representative of the image in a second operating mode; and
- c) processing said test signals from said sensors in said first operating mode.

14. The method according to claim 13 characterised by the step of correcting the image signal output of said sensors in both said first and second operating modes with said compensating signals.

15. The method according to any of claims 12-14, characterised by the step of defocusing said test image.

FIG. 33

The diagram illustrates a video processing system with the following components and signal paths:

- Inputs:**
  - $\emptyset$  (Ground)
  - 591 (Input to AND gate)
  - GRAY SCALE VIDEO (6-bit input to DPCM)
  - GATED LINE SYNC SIGNAL (757)
  - RESET
- Processing Blocks:**
  - DATA FORMATTER (755):** Receives  $\emptyset$  and 591. Outputs CLK (4) and DATA (4).
  - DPCM (754):** Receives GRAY SCALE VIDEO. Outputs CODE (4) to CODE STORAGE.
  - CODE STORAGE (754):** Receives CODE from DPCM. Outputs to DELAY BUFFER (760).
  - DELAY BUFFER (760):** Receives signal from CODE STORAGE. Outputs to SWITCHING SIGNAL (759).
  - LINE SYNC. & SCAN BOUNDARY CONTROL (753):** Receives GATED LINE SYNC SIGNAL (757) and RESET. Outputs SWITCHING SIGNAL (759) and DELAYED LINE SYNC SIGNAL (758).
  - INTERFACE (756):** Receives CLK (4) and DATA (4) from Data Formatter. Outputs CLK and DATA 4.
  - MPU INTERFACE (714):** Receives CLK (715) and DATA (716). Outputs CLK and DATA.
- Signal Paths and Connections:**
  - CLK (4) from Data Formatter (755) is connected to Interface (756) and MPU Interface (714).
  - DATA (4) from Data Formatter (755) is connected to Interface (756) and MPU Interface (714).
  - CODE (4) from DPCM (754) is connected to CODE STORAGE (754).
  - CODE STORAGE (754) is connected to DELAY BUFFER (760).
  - DELAY BUFFER (760) is connected to SWITCHING SIGNAL (759).
  - GATED LINE SYNC SIGNAL (757) and RESET are inputs to LINE SYNC. & SCAN BOUNDARY CONTROL (753).
  - LINE SYNC. & SCAN BOUNDARY CONTROL (753) outputs SWITCHING SIGNAL (759) and DELAYED LINE SYNC SIGNAL (758).
  - SWITCHING SIGNAL (759) is connected to the MPU INTERFACE (714).
  - DELAYED LINE SYNC SIGNAL (758) is connected to the MPU INTERFACE (714).
  - Interface (756) outputs CLK and DATA 4.
  - MPU INTERFACE (714) outputs CLK and DATA.
